Abstract

In this paper, we present a motion planning framework for a fully deployed autonomous unmanned aerial vehicle which integrates two sample-based motion planning techniques, Probabilistic Roadmaps and Rapidly Exploring Random Trees. Additionally, we incorporate dynamic reconfigurability into the framework by integrating the motion planners with the control kernel of the UAV in a novel manner with little modification to the original algorithms. The framework has been verified through simulation and in actual flight. Empirical results show that these techniques used with such a framework offer a surprisingly efficient method for dynamically reconfiguring a motion plan based on unforeseen contingencies which may arise during the execution of a plan. The framework is generic and can be used for additional platforms.

1 Introduction

The use of Unmanned Aerial Vehicles (UAVs) which can operate autonomously in dynamic and complex operational environments is becoming increasingly more common. While the application domains in which they are currently used are still predominantly military in nature, in the future we can expect widespread usage in the civil and commercial sectors. In order to insert such vehicles into commercial airspace, it is inherently important that these vehicles can generate collision-free motion plans and also be able to modify such plans during their execution in order to deal with contingencies which arise during the course of operation. Motion planners capable of dynamic replanning will be an essential functionality in any high-level autonomous UAV system. The motion planning problem, that of generating a collision-free path from an initial to goal waypoint, is inherently intractable for vehicles with many degrees of freedom. Recently, a number of sample-based motion planning techniques [10, 11] have been proposed which tradeoff completeness in the planning algorithm for tractability and efficiency in most cases.

The purpose of this paper is to show how one can incorporate dynamic replanning in such motion planners on a deployed and fully operational UAV by integrating the motion planner with the control kernel of the UAV in a novel manner with little modification of the original algorithms. Integrating both high- and low-end functionality seamlessly in autonomous architectures is currently one of the major open problems in robotics research. UAV platforms offer an especially difficult challenge in comparison with ground robotic systems due to the often tight time constraints present in the plan generation, execution and replanning stages in many complex mission scenarios. It is the intent of this paper to show how one can leverage sample-based motion planning techniques in this respect, first by describing how such integration would be done and then empirically testing the results in a fully deployed system.

An example of the dynamic path replanning experiment is shown in Fig. 1. It shows sample paths generated during the flight in which four no-fly zones were added incrementally. The plan was continuously monitored and repaired as new no-fly zones were added.

The techniques and solutions described are generic in nature and suitable for platforms other than the one used in this experimentation. An important point to note is that to our knowledge we are the first to use these sample-based motion planning techniques with fully deployed UAVs.

The structure of the paper is as follows. First we give an overview of the integrated hardware and software platform used in our UAV. Then an overview of two sample-based motion planning techniques, Probabilistic Roadmaps and Rapidly Exploring Random Trees is provided. Later we describe the basic architecture for integrating motion planners with the UAV control kernel. We explain the path execution mechanism in the static environments and describe the dynamic path replanning scheme in addition to providing timing constraints. At the end the empirical results from experimentation with the deployed system are presented. We then conclude with related work and a summary including future work.
2 WITAS System Overview

2.1 The Hardware Platform

The WITAS 1 UAV platform [6] is a slightly modified Yamaha RMAX helicopter (Fig. 2). It has a total length of 3.6 m (including main rotor) and is powered by a 21 hp two-stroke engine with a maximum takeoff weight of 95 kg. The helicopter has a built-in attitude sensor (YAS) and an attitude control system (YACS). The hardware platform developed during the WITAS UAV project is integrated with the Yamaha platform as shown in Fig. 3. It contains three PC104 embedded computers. The primary flight control (PFC) system runs on a PIII (700Mhz), and includes a wireless Ethernet bridge, a RTK GPS receiver, and several additional sensors including a barometric altitude sensor. The PFC is connected to the YAS and YACS, an image processing computer and a computer for deliberative capabilities. The image processing (IP) system runs on the second PC104 embedded computer (PIII 700MHz), and includes a color CCD camera mounted on a pan/tilt unit, a video transmitter and a recorder (miniDV). The deliberative/reactive (D/R, DRC) system runs on the third PC104 embedded computer (Pentium-M 1.4GHz) and executes all high-end autonomous functionality. Network communication between computers is physically realized with serial line RS232C and Ethernet. Ethernet is mainly used for CORBA applications (see below), remote login and file transfer while serial lines are used for hard real-time networking.

2.2 The Software Platform

A hybrid deliberative/reactive software architecture has been developed for the UAV and has also been used in a ground robot. Conceptually, it is a layered system with deliberative, reactive and control components. The architecture has a reactive concentric flavor where reactive task procedures use services provided by both deliberative and control components in a highly distributed and concurrent manner.

The software implementation is based on CORBA (Common Object Request Broker Architecture), which is often used as middleware for object-based distributed systems. It enables different objects or components to communicate with each other regardless of the programming
languages in which they are written, their location on different processors or the operating systems they running on. A component can act as a client, a server or as both. The functional interfaces to components are specified via the use of IDL (Interface Definition Language). The majority of the functionalities which are part of the architecture can be viewed as CORBA objects or collections of objects, where the communication infrastructure is provided by CORBA facilities and other services such as real-time and standard event channels. This architectural choice provides us with an ideal development environment and versatile run-time system with built-in scalability, modularity, software relocatability on various hardware configurations, performance (real-time event channels and schedulers), and support for plug-and-play software modules. Fig. 4 presents some (not all) of the high-level services used in the WITAS UAV system. Those services run on the D/R computer and interact with the control system.

The control system is a hybrid distributed system that runs primarily on the PFC computer in a real-time environment [13] constructed especially to integrate seamlessly with the rest of the architecture. Hierarchical concurrent state machines (HCSMs) are used to represent system states. The ability to switch modes contingently is a fundamental functionality in the architecture and can be programmed into the task procedures associated with the reactive component in the architecture. We have developed and tested several autonomous flight control modes: takeoff, landing via visual navigation, hovering, dynamic path following, and reactive flight modes for tracking and interception. A CORBA interface is setup on top of the control system kernel so high-level components can issue commands to initiate and sequentialize different flight modes. Helicopter states and events from the control system are in turn sent to the high-level system.

3 The Path Planning Algorithms

In this section, we provide a brief overview of the sample-based path planning techniques used in the experiments. The problem of finding optimal paths between two configurations in a high-dimensional configuration space such as a helicopter is intractable in general. Sample-based approaches such as probabilistic roadmaps (PRM) or rapidly exploring random trees (RRT) often make the path planning problem solvable in practice by sacrificing completeness and optimality.

3.1 Probabilistic Roadmaps

The standard probabilistic roadmap (PRM) algorithm [10] works in two phases, one off-line and the other online. In the off-line phase a roadmap is generated using a 3D world model. Configurations are randomly generated and checked for collisions with the model. A local path planner is then used to connect collision-free configurations taking into account kinematic and dynamic constraints of the helicopter. Paths between two configurations are also checked for collisions. In the on-line or querying phase, initial and goal configurations are provided and an attempt is made to connect each configuration to the previously generated roadmap using the local path planner. A graph search algorithm such as A* is then used to find a path from the initial to the goal configuration in the augmented roadmap.

![Figure 5. PRM path plan generation](image)

Fig. 5 provides a schema of the PRM path planner used in the WITAS system. The planner uses an OBBTree algorithm [7] for collision checking and an A* algorithm for graph search. Here one can optimize for shortest path, minimal fuel usage, etc. The following extensions have been made with respect to the standard version of PRM algorithm in order to adapt the approach to our UAV platform.

- **Multi-level roadmap planning**
  The standard probabilistic roadmap algorithm is formulated for fully controllable systems only. This assumption is true for a helicopter flying at low speed with the capability to stop and hover at each waypoint. However, when the speed is increased the helicopter is no longer able to negotiate turns of a smaller radius.
which imposes demands on the planner similar to non-holonomic constraints for car-like robots. In this case, linear paths are first used to connect configurations in the graph and at a later stage these are replaced with cubic curves when possible. These are required for smooth high speed flight. If it is not possible to replace a linear path segment with a cubic curve then the helicopter has to slow down and switch to hovering mode at the connecting waypoint before continuing. From our experience, this rarely happens.

- **Runtime constraint handling**
  Our motion planner has been extended to deal with different types of constraints at runtime not available during roadmap construction. Such constraints can be introduced at the time of a query for a path plan. Some examples of runtime constraints currently implemented include maximum and minimum altitude, adding forbidden regions (no-fly zones) and placing limits on the ascent-/descent-rate. Such constraints are dealt with during the A∗ search phase.

The mean planning time in the current implementation is below 1000 ms and the use of runtime constraints does not noticeably influence the mean. For a more detailed description of the modified PRM planner, see [14].

### 3.2 Rapidly Exploring Random Trees

The use of rapidly exploring random trees (RRT) provides an efficient motion planning algorithm that constructs a roadmap online rather than offline (Fig. 6).

![RRT Path Plan Generation](image)

**Figure 6. RRT path plan generation**

The algorithm [11] generates two trees rooted in the start and end configurations by exploring the configuration space randomly in both directions. While the trees are being generated, an attempt is made at specific intervals to connect them to create one roadmap. After the roadmap is created, the remaining steps in the algorithm are the same as with PRMs. In comparison with the PRM planner, the mean planning time with RRT is also below 1000 ms, but in this case, the success rate is much lower and the generated plans are not optimal which may sometimes cause anomalous detours [14].

### 4 The Path Execution Mechanism

The standard path execution scheme in our architecture for static operational environments is depicted in Fig. 7.

![Plan Execution Scheme](image)

**Figure 7. Plan execution scheme**

A UAV mission is specified via a task procedure (TP) in the reactive layer of our architecture, (perhaps after calling a task-based planner). A TP is a high-level procedural execution component which provides a computational mechanism for achieving different robotic behaviors. For the purposes of this paper, it can be viewed as an augmented state machine.

For the case of flying to a waypoint, an instance of a navigation TP is created. First it calls the path planner service (step 1) with the following parameters: initial position, goal position, desired velocity and additional constraints. If successful, the path planner (step 2) generates a segmented cubic polynomial curve. Each segment is defined by start and end points, start and end directions, target velocity and end velocity. The TP sends the first segment (step 3) of the trajectory via the control system interface and waits for the Request Segment event that is generated by the controller.

At the control level, the path is executed using a Dynamic Path Following (DPF) controller [5] which is a reference controller that can follow cubic splines. When a Request Segment event arrives (step 4) the TP sends the next segment. This procedure is repeated (step 3-4) until the last segment is sent. However, because the high-level system is not implemented in hard real-time it may happen that the next segment does not arrive at the control kernel on time. In this case, the controller has a timeout limit after which it goes into safety braking mode in order to stop and hover at the end of the current segment. The timeout is determined by a velocity profile, current position and current velocity.
Fig. 8 depicts a timeline plot of the execution of a trajectory (2 segments). At time \( t_0 \), a TP sends the first segment of the path to the DPF controller and waits for a Request segment event which arrives immediately (\( t_1 \)) after the helicopter starts to fly (\( t_{start1} \)). Typical time values for receiving a Request segment event (\( t_1 - t_0 \)) are well below 200ms. Time \( t_0 \) is the timeout for the first segment which means that the TP has a \( \Delta t_{timeout} \) time window to send the next segment to the DPF controller before it initiates the safety braking procedure. If the segment is sent after \( t_0 \), the helicopter will start braking. In the current implementation, segments are not allowed to be sent after the timeout. This will be changed in a future implementation. In practice the \( \Delta t_{timeout} \) time window is large enough to replan the path using the standard path planner. The updated segments are then sent to the DPF controller transparently.

5 Dynamic Replanning of the Path

There are several services that are used during path replanning stage. They are called when changes in the environment are detected and an update event is generated in the system. The augmented state machine associated with the TP used for the dynamic replanning of the path is depicted in Fig. 9. The TP takes the start and the end point and the target velocity as input. The TP then calls a path planning service (Plan state) which returns an initial path.

If the helicopter is not aligned with the direction of the flight, a command to align is sent to the controller (Align state). The TP then sends the first segment of the generated path to the DPF controller (Send segment state) and calls the Prediction service to estimate a timeout for the current segment (Estimate timeout state). Based on the segment timeout and system latency, a condition is calculated for sending the next segment. If there is no change in the environment the TP waits (Wait state) until a timeout condition is true and then sends the next segment to the DPF controller.

In case new information about newly added or deleted forbidden regions (no-fly zone updated) arrives, the TP checks if the current path is in collision with the updated world model (Check Collision state). If a collision is detected in one or more segments the TP calls a Strategy Selector service (Strategy Selection state) to determine which replanning strategy is the most appropriate to use at the time. The Strategy Selector service uses the Prediction service for path timings estimation (Times Estimation state) to get estimated timeouts, total travel times etc. It also uses the Strategy Library service (Strategy Library state) to get available replanning strategies that will be used to replan when calling the path planner (Replan state).

The TP terminates when the last segment is sent. More details on the Strategy Selector service, the Strategy library and the Prediction service will follow in the next subsections.

5.1 Prediction Service

All time estimations that have to do with paths or part of the paths are handled by the Prediction service. It uses the velocity profile of the vehicle and path parameters to calculate timeouts, total times, and combinations of those.
For instance, in the case of flying a two-segment trajectory (see execution timeline in Fig. 8) it can estimate time-outs ($\Delta t_{1\text{timeout}}$, $\Delta t_{2\text{timeout}}$), total travel times ($\Delta t_{1\text{total}}$, $\Delta t_{2\text{total}}$) as well as a combined timeout for the first and the second segment ($t_{\text{to2-t1}}$).

5.2 Strategy Library

When part of the path is not valid anymore, the path planner service can be called in order to repair an existing plan or to create a new one. There are many strategies that can be used at that step which can give different results depending on the situation.

- **Strategy 1**
  Replanning is done from the next waypoint (start point of the next segment) to the end point. This implies longer planning times and eventual replacement of collision-free segments that could be reused. The distance to the obstacle in this case is usually large so the generated path should be smoother and can possibly result in a shorter flight time.

- **Strategy 2**
  Segments up to the colliding one are left intact and replanning is done from the last collision-free waypoint to the end point. In this case, planning times are cut down and some parts of the old plan will be reused. But since the distance to the obstacle is shorter than in the previous case, it might be necessary for the vehicle to slow down at the joint point of two plans, this can result in a longer flight time.

- **Strategy 3**
  Replanning is done only for colliding segments. The helicopter will stay as close to the initial path as possible.

- **Strategy 4**
  There can be many other strategies that take into account additional information that can make the result of the replanning better from a global perspective. An example can be a strategy that allows new pass waypoints that should be included in the repaired plan.

Note that each of these strategies progressively re-uses more of the plan that was originally generated, thus cutting down on planning times but maybe producing less optimal plans. The decision as to which strategy to use is made by the Strategy Selector service described in the next subsection.

5.3 Strategy Selector Service

The Strategy selector service is responsible for choosing the strategy or strategies to execute in the event of path occlusion. It keeps track of the time that it uses, so that always valid path is available when the timeout condition becomes true. The Strategy Selector holds information as to which segments of the path were invalidated and it can use the Prediction service to get estimated timings for the path or parts of the path. Based on that and available strategies (from the Strategy Library) it can make a decision which strategy or strategies to use for replanning at the current time. If many strategies are applied and more new plans are generated, it also evaluates them according to a given optimization criterion that is declared by the user or another service. For instance, if the time window for making a decision about the next segment is short then the fastest strategy is used in order to produce a valid plan on time.

The Strategy Selector is also responsible for updating information about strategies in the Strategy Library, in particular estimated execution times. The same strategies in different environments might require less or more time for execution. That information is fed back to the library, so the next time the Strategy Selector has more accurate information about the execution time and can make a better decision which strategy to apply.

6 Generic Nature of the Framework

The proposed framework is generic and can be used with additional platforms. This implies using different segment parameters that are more fitted to the platform capabilities. Fig. 11 shows the dependency between the minimum distance to detect the obstacle and velocity of the vehicle in order to make one path replanning. This plot is valid for our helicopter platforms. This is the worst case under the assumption of constant velocity along the path. Acceleration and deceleration is equal to $1.6 \text{ m/s}^2$. The minimum
time for one replanning including system latency is below 1200 ms.

![Figure 11. Critical distance for detecting an obstacle](image)

A similar plot can be created for other platforms and based on the desired flight envelope the choice of the preferred parameters of the segments can be made. Additionally some modifications to the path planners itself are necessary because of the different characteristics of the controller. Other than that, the idea of executing parts of the plan in the form of segments and using estimated time widows to adapt the plan to the changes in the environment would still apply.

7 Experimental Results

In our experiments we have used both the PRM and the RRT planner. We included the first three strategies from the Fig. 10 in the Strategy Library. During the flight forbidden regions were randomly added by the ground operator. In order to compare the performance of different strategies only one strategy was used per experiment.

Typical values of parameters related to the execution and the planning phases are presented in Tables 1 and 2. The number of segments is taken from the final path.

Observe that in the case of Strategy 1 (Table 1), \( \Delta_t \) (time window for replanning) is generally greater than four times the amount of time required to generate full plans using either the PRM or RRT planners.

The difference is even greater (up to 20 times) in the case of Strategy 3 (Table 2). This is as expected, the more the existing plan is reused the less time is needed to repair it. Although, replanning times for applying Strategy 3 are much smaller, the paths have much more segments (up to 15). Such paths usually imply a smaller average velocity which can result in a longer flight time.

8 Related Work

Finding collision-free paths in dynamically changing environments is an open research problem in the motion planning community. As important as the problem is there are a limited number of contributions that address issues related to changing environments and even less in the context of UAVs. Results using probabilistic roadmap based planners focus mainly on the mobile manipulation domain (e.g. [9], [12]). An example of planner that samples state \( \times \) time space in order to deal with kinematic and dynamic constrains on robots, as well as moving obstacles is presented by [8]. Some work has also been done with the elastic framework ( [2], [3], [4]) and with decomposition-based methods [1]. In the UAV domain, we believe we are the first to apply sample-based motion planning approaches.

9 Conclusions and Future Work

The planning framework that has been described in this paper was tested and used in a fully deployed autonomous UAV system. We have presented a distributed software architecture for UAVs and considered how one can successfully integrate sample-based motion planning techniques in a robust and efficient manner. We have also shown how these techniques can be used to deal with contingencies such as new no-fly zones during plan execution. This has been done by analyzing the course of plan execution and extracting upper bounds on the time that can be spent gen-

In the future we would like to improve the efficiency of the framework by working on the path planning algorithms. This would also include extending the framework to handle different platforms than helicopters e.g. fixed wing. Another interesting issue is extending the Strategy Library to include additional external information e.g. weather conditions. Some work will be put into the Strategy Selector service which is a key component in the framework.
